Introduction

We build media mix models. So a guide titled *when not to build one* deserves a word of explanation.

Over the years, MMM engagements succeed or fail for reasons that have almost nothing to do with modeling skill. This guide names seven scenarios in which we would genuinely advise against commissioning an MMM, at least for now.

Each scenario reflects a **structural problem, not a modeling inconvenience**. No amount of Bayesian priors, hierarchical pooling, or machine-learning cleverness will fix data that carries no signal, a history too short to reveal effects, or channels that never move independently. A model can only learn what the data is willing to reveal.

If, after reading, you conclude that an MMM is right for your business, we would welcome the conversation. If you conclude it is not (or not yet), we consider that a good outcome as well. Both of us avoid an expensive disappointment.

SCENARIO 01

Not enough spend variance

The symptom

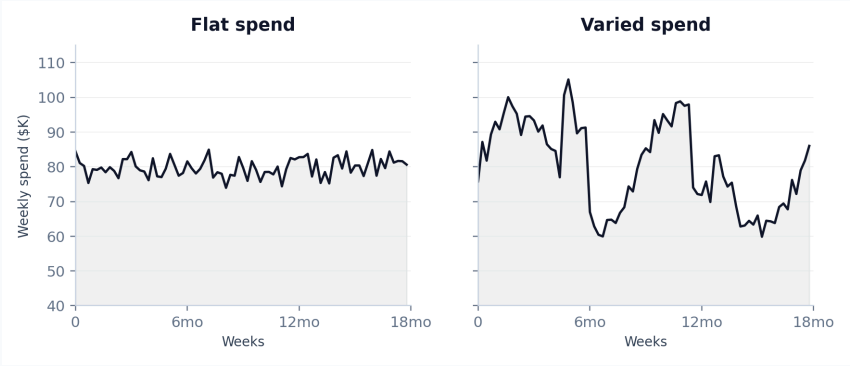
Your media budget has been broadly steady for a long time. Meta has held at roughly $80K per week, give or take ten percent, for the last eighteen months. Search has been close to a fixed share of the mix. TV runs in the same flight pattern each quarter.

Why MMM fails here

An MMM identifies each channel's effect by watching how outcomes move when spend changes. With little variation in the input, there is little for the model to learn from. The likely outputs are credible intervals so wide that no budget recommendation is actionable, or coefficients that look precise but are fitted to noise. Both look like answers. Neither is one.

What to do instead

Create the variation deliberately. Holdout weeks, geo-level pulses, or short shock tests on individual channels generate the variance an MMM needs. If the business is unwilling to perturb spend, consider that your measurement budget may be better spent on incrementality tests, where you will get an actionable signal. Then layer that with some marginal analysis (i.e. what the last $100K of spend actually got you), and you can then make budget decisions.



An MMM can learn from the chart on the right. The chart on the left contains almost no information for the model.

SCENARIO 02

Not enough historical data

The symptom

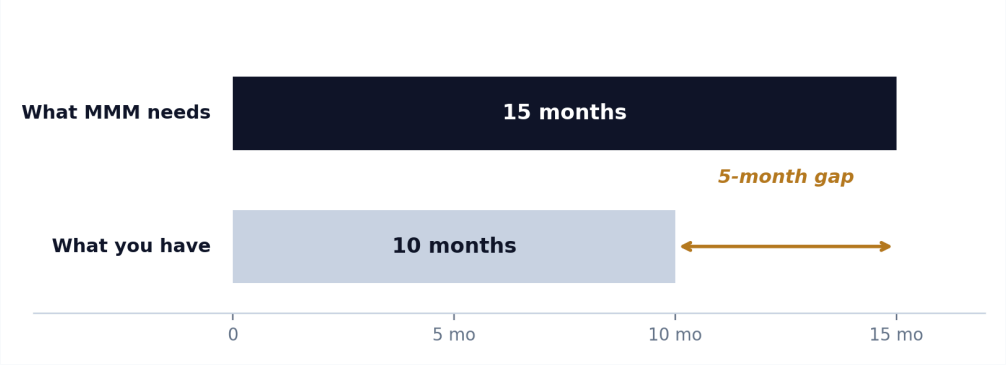
Your business is young, recently re-platformed, or lost data continuity in a tracking reset. You have less than twelve months of clean data.

Why MMM fails here

A mix model needs enough history to observe seasonality, slow channel decay, and the interaction between them. The practical minimums are roughly fifteen months to get some year-over-year seasonality into the modeling as well. If your business has strong annual seasonality, you want to observe each season at least twice to separate it from media effect. Shorter histories force the model to confound media and season, and the results reflect that confusion. However, note that there is a tradeoff here. If your older data is no longer reflective of your current business, then you may want to leave that data out.

What to do instead

Fix the data foundation first. The cost of collecting another few months of clean daily data is trivial compared with the cost of decisions based on a confused model. In the interim, use experimental methods: geo holdouts, matched-market tests, difference-in-differences — to answer the specific questions that cannot wait.



The gap is not a modeling problem. It is an observation problem.

SCENARIO 03

One channel dominates

The symptom

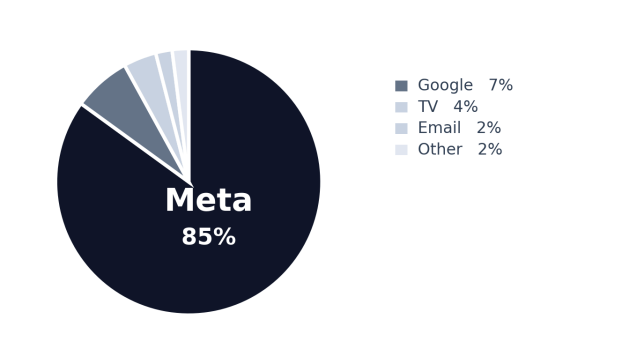
One channel accounts for more than roughly eighty percent of your spend. Often it is Meta; sometimes Google Search; occasionally Amazon or a single affiliate partner.

Why MMM fails here

When a single channel dominates, every other channel carries too little variance and contribution to be estimated reliably. The model's estimates for small channels will come with enormous uncertainty, and its recommendation to shift five or ten percent of budget elsewhere will rest on confidence intervals that span useless territory. Meanwhile, the dominant channel's effect is usually evident without a model: you can see it in the daily numbers whenever you pause it.

What to do instead

Run a geo holdout on the dominant channel (or if the channel impact is same-day, consider an on/off test). Turn it off in ten to fifteen percent of geographies for four to six weeks and measure the revenue impact directly. You will learn more, faster, and for less money than an MMM would provide at this stage. Once the portfolio rebalances and no channel exceeds roughly forty percent, the conditions for a useful MMM begin to emerge.



Statistical methods struggle to estimate the small wedges with any useful precision.

SCENARIO 04

Perfectly confounded channels

The symptom

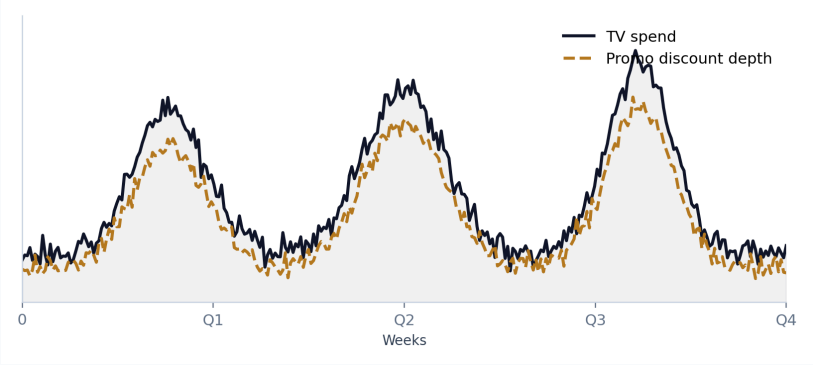
Every TV flight lands the same week as a storewide promotion. Paid social scales up every December alongside every other holiday driver. Pricing changes consistently accompany new creative launches.

Why MMM fails here

An MMM separates the effects of drivers by observing them move independently. When two drivers always move together, no model can mathematically identify their separate contributions.

What to do instead

Break the confounding deliberately. Stagger media flights and promotional windows by two to three weeks. Alternate pricing tests across geographies. If deliberate separation is not operationally feasible, answer the highest-priority questions with controlled experiments that isolate one variable at a time, and defer the full mix model until the data can support it.



If two drivers always move together, neither can be estimated in isolation.

SCENARIO 05

No priors for long-carryover channels

The symptom

A meaningful share of your spend sits in channels with slow decay: television, out-of-home, podcast, connected TV, and some upper-funnel digital. You have not run incrementality tests on those channels, and you have no documented subject-matter priors about their half-life.

Why MMM fails here

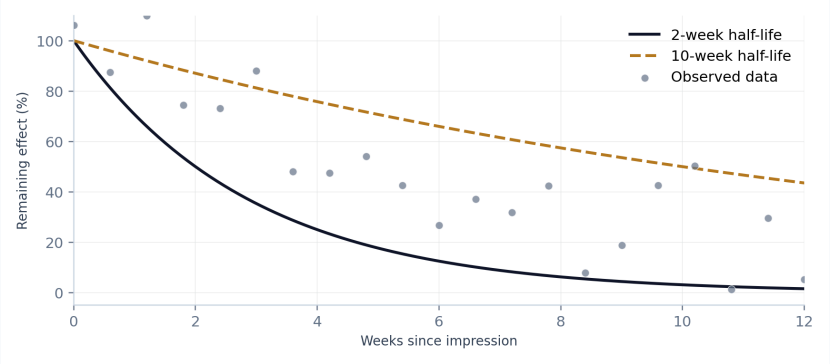
Adstock parameters, which govern how quickly a channel's effect decays over time, are notoriously hard to identify from data alone. A two-week half-life and a ten-week half-life can fit the same noisy historical data almost equally well. Without strong priors, the optimizer settles on whichever value reduces in-sample error fractionally more, and reports it with false precision. The consequence is not an obviously wrong answer. It is a plausible-looking answer that may be meaningfully off, with no internal signal to flag the problem.

There are essentially three ways to pin down carryover:

- Years of spend variance wide enough that the data itself identifies the decay. Rare.
- Subject-matter priors informed by brand research or industry benchmarks. Better, but external.
- Incrementality tests, specifically dark-week or holdout studies on the long-decay channel, that measure the carryover directly. Best.

What to do instead

Commission a small carryover study on your largest long-decay channel. A four-to-six-week dark-week test on TV, for example, is enough to estimate the half-life within a useful range. Feed that result into the MMM as a prior. The model now has an anchor, and its output for that channel becomes defensible.



Both curves fit the data. Only one is right. Without a prior, the model cannot tell

SCENARIO 06

You need a different tool

The symptom

The decision you actually need to make is narrower than *how should I reallocate budget across channels month by month*.

Why MMM fails here

An MMM answers strategic budget-allocation questions on monthly or quarterly cycles. It does not answer:

- **Which keywords are working?** That is attribution or platform-level reporting.
- **Did this specific campaign drive incremental lift?** That is an incrementality test.
- **Should I change my Meta CPA bid this afternoon?** That is bid optimization.
- **Which creative variant is winning?** That is a creative test.

Using an MMM to answer any of these is slower and less accurate than the method purpose-built for the question. Worse, the wrong answer arrives with the authority of a six-figure engagement behind it.

What to do instead

Write down the decision you actually need to make. Match the decision to the right method. In most mature programs, MMM, incrementality testing, and platform-level attribution work together as a system: MMM for strategic allocation, incrementality for calibration and new-channel validation, attribution for tactical optimization.

THE QUESTION		THE RIGHT METHOD
Strategic quarterly reallocation	→	**MMM**
Did this test actually work?	→	**Incrementality test**
Daily campaign optimization	→	**Attribution / platform reporting**

Each method answers a different question. Choose before you commission.

SCENARIO 07

You will not require out-of-sample validation

The symptom

The model review process in your organization, or your vendor's standard deliverable, stops at in-sample fit statistics. R-squared and the shape of the fitted curve are presented; out-of-sample predictive error is not.

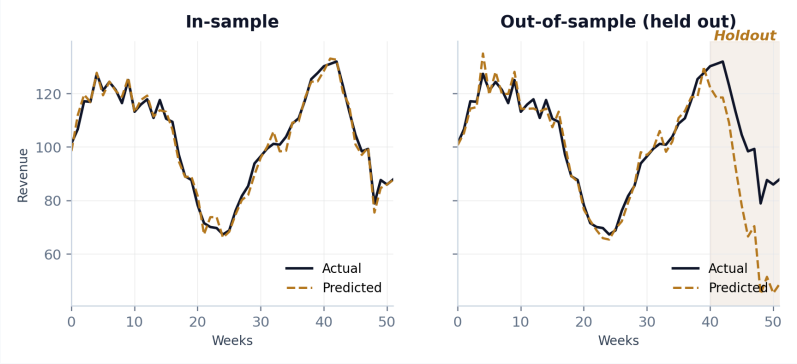
Why MMM fails here

If the model has overfitted the data, it will seemingly perform well on training data but fail on unseen data (which is where you really want it to perform well). And the only reliable way to test for this before actioning on the model's recommendations is to test the model on data it has not seen. The industry default is in-sample fit, which rewards models that interpolate history well and penalizes nothing about their ability to predict forward. A model that fits yesterday's data perfectly and predicts next month's outcomes poorly is not a useful planning tool.

Walk-forward validation is the minimum acceptable standard. Hold out the most recent N weeks. Fit the model on the rest. Predict the holdout. Measure mean absolute percentage error (MAPE). Repeat on a rolling basis. A healthy model, for most consumer businesses with sufficient data, lands within roughly ten to fifteen percent MAPE on truly unseen periods. Anything materially worse suggests the model is learning history rather than predicting the future.

What to do instead

Before signing an MMM engagement, ask the vendor a single question: **what out-of-sample MAPE will you commit to, and how will you report it?** Require walk-forward validation in the scope of work.



In-sample fit is easy. Out-of-sample prediction is the only number that matters for forward-looking decisions.

If none of these apply, you're in good shape.

If you have spend variance, sufficient history, balanced channels, staggered campaigns, priors or tests for long-decay channels, a clear separation between strategic and tactical measurement questions, and an appetite for out-of-sample rigor, an MMM is likely to reward you with genuine insight and defensible budget recommendations.

A final observation, less technical than the seven above: **the organizational appetite to act on results.** The best MMM in the world generates no ROI if the team that owns the budget will not reallocate based on the output. Before commissioning an MMM, ask your channel leads whether they would accept a credible recommendation to shift up to 20 percent of spend away from their channel — or toward it.
